Abstract
Gabbay’s separation theorem is a fundamental result for linear temporal logic (LTL). We show that separating a restricted class of LTL formulas, called anchored LTL, is elementary if and only if the translation from LTL to the linear temporal logic with only future temporal connectives is elementary. To prove this result, we define a canonical separation for LTL, and establish a correspondence between a canonical separation of anchored LTL formulas and the $\omega$-automata that recognize these formulas.

The canonical separation of anchored LTL formulas has two further applications. First, we constructively prove that the safety closure of any LTL property is an LTL property, thus proving the decomposition theorem for LTL: every LTL formula is equivalent to the conjunction of a safety LTL formula and a liveness LTL formula. Second, we characterize safety, liveness, absolute liveness, stable, and fairness properties in LTL. Our characterization is elementary: We reduce the problem of deciding whether an LTL formula defines any of these properties to the validity problem for LTL.

Keywords Linear Temporal Logic, $\omega$-automata, Safety, Liveness

1. Introduction
The linear temporal logic with both past and future temporal connectives (FLTL) and the linear temporal logic with only future temporal connectives (FLTL) are equally expressive [GPSS80]. This is because one can translate from LTL to FLTL using Gabbay’s separation algorithm [G87]. This may result in a nonelementary blow-up in the formula size.

The exact status of the blow-up is less clear than the succinctness gap. The latter gap has been shown to be nonelementary [HR05]. The former belief has been folklore, possibly due to a misinterpretation of Wilke’s construction of FLTL formulas from counter-free automata on finite words [W99]. A result connects the succinctness gap to the complexity of separating any strict subset of LTL formulas, called anchored formulas.

We use Gabbay’s separation theorem, stating that every LTL formula can be rewritten into a separated form, i.e. as a Boolean combination of future-only formulas and past-only formulas. We introduce a canonical form for separated formulas with a unique structure that simplifies our reasoning. We focus on the canonical form of anchored LTL formulas. An anchored formula has the property that its semantics is the same at each moment in time. Intuitively, such a formula is bounded to the initial time. For any given formula, we can obtain an equivalent anchored formula using simple syntactic manipulation.

Canonical separation of anchored formulas has two useful features. First, to translate an LTL formula $\varphi$ into FLTL it suffices to separate its anchored equivalent. Second, separating anchored formulas appears to be easier than separating arbitrary formulas: We show that there is an elementary algorithm for separating anchored formulas if and only if there is an elementary algorithm for translating LTL to FLTL.

Canonical separation of anchored formulas is of further interest. We constructively prove that any property expressible in LTL is the intersection of a safety property and a liveness property, both expressible in LTL. This sharpens Alpern and Schneider’s safety-liveness decomposition [AS87] for $\omega$-regular languages, and improves on our previous construction [PMTDB]. As a side result, we constructively show that for any safety LTL formula $\varphi$, there is a one-to-one correspondence between the conjuncts of any canonical separation of anchored $\varphi$ and the states of a minimal deterministic Büchi automaton that recognizes the language of $\varphi$: see Section 5.2. Furthermore, we characterize safety, liveness, absolute liveness, stable and fairness LTL formulas in terms of the separation of their anchored equivalents. The characterizations are effective, reducing the decision problem of recognizing such formulas to the validity problem for LTL.

Road Map. In Section 2 we recall linear temporal logic, safety and liveness, and $\omega$-automata. In Section 3 we introduce canonical separation, and in Section 4 we relate the canonical separation of anchored formulas to Büchi automata, thereby relating the problem of separating anchored formulas to the problem of translating LTL to FLTL. In Section 5 we introduce an equivalence relation on the set of finite traces that generalizes the canonical separation of anchored formulas to arbitrary properties. Furthermore, we characterize safety and liveness in terms of this equivalence relation, constructively proving that the safety closure of every LTL formula is in LTL, and that LTL can be decomposed into safety and liveness within LTL. In Section 6 we characterize stable, absolute live-
ness, and fairness properties in LTL. In Section 7 we discuss related work.

2. Preliminaries

For a finite set $AP$ of atomic propositions, we fix the alphabet $Σ = 2^{AP}$. Let $Σ^∗$ be the set of all countably infinite sequences over $Σ$, $Σ^ε$ be the set of all finite nonempty sequences over $Σ$, and $Σ^ε = Σ^∗ ∪ \{ε\}$, where $ε$ is the empty sequence. An element of $Σ^∗$ is a path, and a property is any set of paths. A trace is an element of $Σ^∗$. The length of a trace $t = p_0 p_1 ⋅ ⋅ ⋅ p_n$, denoted $|t|$, is $i + 1$.

For a path $π = p_0 p_1 p_2 ⋅ ⋅ ⋅$, its prefix $π_i$ is the trace $p_0 p_1 ⋅ ⋅ ⋅ p_i$, and its suffix $π_i$ is the path $p_i p_{i+1} ⋅ ⋅ ⋅$. For a trace $t$ and a path (or a trace) $π$, the concatenation of $t$ and $π$ is denoted $t \pi$. The concatenation of $π$ and $\pi$ is $π \pi$.

2.1 Linear Temporal Logic

Our definitions in this section are standard; see for example [G87, M03, HR05].

Definition 1 (LTL Syntax). The syntax of Linear Temporal Logic, LTL, is given by the grammar

$$ϕ ::= T | a | ¬ϕ | ϕ ∨ ψ | ϕ ∧ ψ | ● ϕ | χ ϕ | ψ △ ϕ,$$

where $a ∈ AP$. We write $⊥$ for $¬T$, $ϕ ψ$ for $¬ϕ ∨ ψ$, $ϕ ⇔ ψ$ for $(ϕ → ψ) ∧ (ψ → ϕ)$, $ϕ S ψ$ for $T S ϕ$, $ϕ △ χ$ for $¬T △ χ$, $ϕ ◊ T ϕ$ for $¬⊥ ϕ$, $ϕ △ ψ$ for $¬T ϕ$.

The size of an LTL formula is defined inductively over its structure: $|T| = 1, |a| = 1$ for $a ∈ AP, |ϕ ∨ ψ| = |ϕ| + |ψ|$ for $ϕ ∈ \{¬, ∨, ∧, ●, ◊, △, ◊ T, △ T\}$.

Definition 2 (LTL Semantics). For a path $π = p_0 p_1 p_2 ⋅ ⋅ ⋅$ and $i ∈ N$, the satisfaction relation $\models$ for LTL formulas is defined inductively over the formula structure:

$$\begin{align*}
π, i &\models T \quad \text{if } i < |π|, \\
π, i &\models a \quad \text{if } a \in p_i, \\
π, i &\models ¬ϕ \quad \text{if } π, i + i \not\models ϕ, \\
π, i &\models ϕ ∨ ψ \quad \text{if } π, i \models ϕ \text{ or } π, i \not\models ψ, \\
π, i &\models ϕ ∧ ψ \quad \text{if } π, i \models ϕ \text{ and } π, i \models ψ, \\
π, i &\models ● ϕ \quad \text{if } i > 0 \text{ and } π, i − 1 \models ϕ, \\
π, i &\models ○ ϕ \quad \text{if } i = 0 \text{ and } π, i \models ϕ, \\
π, i &\models ϕ △ ψ \quad \text{if } π, j \models ψ \text{ for all } j < k \leq i, \\
π, i &\models ϕ ◊ T ψ \quad \text{if } π, j \models ψ \text{ for all } j < k \leq i, \text{ and } π, k \models ψ \text{ for all } i \leq k < j.
\end{align*}$$

When $π, i \models ϕ$, we say $ϕ$ is satisfied at time $i$ and we say $ϕ$ is satisfiable if there is a path $π$ such that $π, 0 \models ϕ$. The formula $ϕ$ is valid if $¬ϕ$ is not satisfiable. An LTL formula $ϕ$ expresses the property $L(ϕ) = \{π ∈ Σ^∗ | π, 0 \models ϕ\}$.

A past LTL formula is a formula that does not use the future temporal connectives $⊙$ and $△ T$. A future LTL formula is a formula that does not use the past temporal connectives $●$ and $S$.

Lemma 3. Let $F$ be a future formula and let $P$ be a past formula. Then for every $i ∈ N$ and every path $π ∈ Σ^∗$

1. $π, i \models F$ iff $π, i | F$, for every trace $c ∈ Σ^∗$, and
2. $π, i \models P$ iff $π, σ, i \models P$, for every path $σ ∈ Σ^∗$.

Informally, the satisfaction of future formulas is independent of changing the past and the satisfaction of past formulas is independent of changing the future. This justifies the following definition of satisfaction for past formulas on finite traces. For a past formula $P$ and a trace $t ∈ Σ^∗$, we write $[t, |t| − 1] \models P$, for any path $π$.

Definition 4. We define two equivalence relations on LTL formulas.

1. The formulas $ϕ$ and $ψ$ are globally equivalent, denoted $ϕ \equiv_1 ψ$, if $π ∈ Σ^∗$, $i ∈ N, (π, i) ≡ ϕ \iff i ≡ ψ$, $π, i \models ϕ$.
2. The formulas $ϕ$ and $ψ$ are initially equivalent, denoted $ϕ \equiv_2 ψ$, if $π ∈ Σ^∗$, $(π, 0) ≡ ϕ \iff i ≡ ψ$.

Global equivalence implies initial equivalence, but the converse is false. For example, the formulas $T$ and $⊥$ are initially equivalent, but they are not globally equivalent. Note that $ϕ \equiv_2 ϕ$ if and only if $L(ϕ) = L(ψ)$. Checking the global equivalence of $ϕ$ and $ψ$ can be reduced to the validity problem for LTL. Namely, $ϕ \equiv_2 ψ$ if and only if the formula $L(ϕ) ↔ L(ψ)$ is valid.

The separation theorem of Gabbay [G87] states that every LTL formula is globally equivalent to a Boolean combination of past and future formulas. Furthermore, Gabbay gives an algorithm for separation. It is easy to rewrite Gabbay’s Boolean combination as a conjunction of implications as stated in the following theorem.

Theorem 5 (LTL Separation). Each LTL formula $ϕ$ is globally equivalent, through a sequence of rewrites, to a formula

$$(P_1 \circ F_1) ∧ ⋯ ∧ (P_n \circ F_n),$$

where $P_i$ are past formulas and $F_i$ are future formulas.

We call this formula a separation of $ϕ$. We write $(P → F)_{\alpha}$ to denote a separation consisting of $κ$ conjuncts. Each conjunct is an implication $P_i → F_i$, and we call the formulas $P_i$ and $F_i$ the past part and the future part of the conjunct, respectively.

We remark that Gabbay’s algorithm results in a nonelementary blow-up: there is no constant $k ∈ N$ such that for any formula $ϕ$ the size of its separation is bounded from above by a $k$-ary exponential function in the size of $ϕ$; for a definition of nonelementarity complexity see [M74]. We refer to the minimum blow-up in the formula size that is introduced by separation as the separation gap. The exact status of the separation gap is an open problem [HR05].

Example 6. We use the formula $ϕ = □a → ◊ b$ as our running example. This formula expresses a simple precedence property, for example that access to some resource $(a)$ must be preceded by a request $(b)$. A separation of $ϕ$ is given by the formula

$$ψ = (□¬b ∧ a) → □ ⊥) ∧ (□¬a → □(a ∨ ¬b)).$$

Intuitively, with no requests in the past, access is prohibited in the present, and a request will be made in the future before the first access, or no access will ever be made in the future.

2.2 Safety and Liveness

According to Lamport [L77], a safety property states that something “bad” never happens. For example, the elevator door never opens while the elevator is moving. A liveness property states that something “good” eventually happens. For example, every process in a multitasking system will eventually be granted CPU time. There are various formalizations of safety and liveness, such as [LPZ85], but Alpern and Schneider’s formalization [AS85] has become widely accepted.

Definition 7 ([AS85]). A set $S$ of paths is a safety property if for every $π ∈ S$ there is an $i ∈ N$ such that $π, σ ∈ S$ for all $σ ∈ Σ^∗$.

A set $L$ of paths is a liveness property if for every $π ∈ Σ^∗$ there is a path $π$ such that $π ≡ i ∈ L$.

Intuitively, every path that is not in a safety property $S$ has a finite “bad” prefix, while every trace has a “good” suffix for a liveness property $L$. For an LTL formula $ϕ$, we say $ϕ$ is a liveness, respectively safety, formula if $L(ϕ)$ is a liveness, respectively safety, property. From this point on, whenever confusion is unlikely, we identify a formula with the property it expresses.

Every property can be expressed as the intersection of a safety property and a liveness property [AS85]. Moreover, for every property $ϕ$ we can define its safety closure $[ϕ]$ as the smallest safety
property containing \( L \). In [PMTDB], we prove that for every property expressible in LTL, its safety closure is also expressible in LTL. As a consequence, the decomposition into safety and liveness is possible within LTL.

**Theorem 8** ([PMTDB]). For every LTL formula \( \varphi \), the safety closure \([\text{L}(\varphi)]\) of \( L(\varphi) \) is expressible by an LTL formula. ▲

**Theorem 9** (Safety-Liveness Decomposition in LTL [PMTDB]). For every LTL formula \( \varphi \), there are LTL formulas \( \sigma \) and \( \lambda \) such that \( L(\sigma) \) is safety, \( L(\lambda) \) is liveness, and \( \varphi \equiv \sigma \land \lambda \). ▲

In Section 5.2 we use canonical separation to constructively prove these theorems and to characterize safety and liveness in LTL. See Section 7 for our comparison with [PMTDB].

### 2.3 \( \omega \)-automata

We assume that the reader is familiar with automata on finite words and regular expressions. For background see [H79, M71]. We take the definition of Büchi automata from [T90].

**Definition 10.** A Büchi automaton over the alphabet \( \Sigma \) is a tuple \( \mathcal{A} = (Q, q_0, \Delta, F) \) with a finite set \( Q \) of states, an initial state \( q_0 \in Q \), a transition relation \( \Delta \subseteq Q \times \Sigma \times Q \), and a set \( F \subseteq Q \) of accepting states. A Büchi automaton is deterministic if \( \Delta \subseteq Q \times \Sigma \rightarrow Q \) is a partial transition function.

A run of \( \mathcal{A} \) on a path \( \pi = p_0p_1 \cdots \in \Sigma^\omega \) is a sequence of states \( s_0s_1 \cdots \in Q^\omega \) such that \( s_0 = q_0 \) and \( (s_i, p_i, s_{i+1}) \in \Delta \) for \( i \in \mathbb{N} \). The run is accepting if some state of \( F \) occurs infinitely often in the run. \( \mathcal{A} \) accepts \( \pi \) if there is an accepting run of \( \mathcal{A} \) on \( \pi \). The property \( L(\mathcal{A}) = \{ \pi \in \Sigma^\omega \mid \mathcal{A} \text{ accepts } \pi \} \) is the property recognized by \( \mathcal{A} \).

For \( t \in \Sigma^\ast \) we define \( (s, t, s') \in \Delta^\ast \) if there is a sequence of states \( s_0s_1 \cdots s_{i+1} \) such that \( s = s_0 \), \( t = s_i \), and \( (s_{i+1}, a, s_{i+2}) \in \Delta \) for \( 0 \leq i \leq |t| \).

For a non-deterministic Büchi automaton, we allow a set of initial states \( Q_0 \subseteq Q \) instead of a single state \( q_0 \). Formally, the notation \( \mathcal{A} = (Q, Q_0, \Delta, F) \) is a short-hand for the automaton \( \mathcal{A'} = (Q \cup \{q_0\}, q_0, \Delta', F) \), where \( q_0 \notin Q \) and the relation \( \Delta' \) is defined as follows. For all states \( p, q \in Q \cup \{q_0\} \) and every \( a \in \Sigma \), the tuple \( (p, a, q) \) is in \( \Delta' \) if \( (p, a, q) \in \Delta \) or \( p = q_0 \) and there is a state \( s \in Q_0 \) such that \( (s, a, q) \in \Delta \).

Several types of \( \omega \)-automata have been studied in the literature. These include generalized Büchi automata; see for example [G001]. They differ from Büchi automata only in their acceptance condition. In a generalized Büchi automaton, we have \( F \subseteq 2^\Sigma \) and a run is accepting if it visits at least one element from each set in \( F \) infinitely often.

### 3. Canonical Separation

We start with an informal account of canonical separation and anchored formulas and provide the definitions afterward.

Consider the following scenario. A system that has been running for some time is required to satisfy a property expressed by an LTL formula \( \varphi \) (at the initial moment in time). The past behavior, logged as a trace \( t \), determines which future system behavior is allowed and which would falsify \( \varphi \). Intuitively, a separated formula \( \psi = (P_0 \rightarrow \Diamond F_0) \land \cdots \land (P_n \rightarrow \Diamond F_n) \) has a suitable structure for this scenario: the past formulas \( P_i \) stand for the possible parts, while the corresponding future formulas \( F_i \) describe the allowed futures. Specifically, our goal is to produce a separated formula \( \psi \) such that for every trace \( t \) there is a unique index \( i \) such that \( t \models P_i \) (determines the past) and that for every path \( \pi \) the path \( \pi \) satisfies \( \varphi \) if and only if \( \pi \models F_i \). We will show that \( \psi \not\models \varphi \), but \( \psi \) can be constructed from \( \varphi \). We require that the separation \( \psi \) meets the following conditions.

1. For every \( t \in \Sigma^\ast \), there is a unique \( i \) such that \( t \models P_i \).
2. For every \( \pi \in \Sigma^\omega \), if there is a \( k \in \mathbb{N} \) such that \( \pi, k \models \varphi \) then \( \pi, 0 \models \varphi \).
3. For every \( \pi \in \Sigma^\omega \), if \( \pi, 0 \models \varphi \) then \( \pi, k \not\models \psi \), for any \( k \in \mathbb{N} \).
4. For all \( i, j \), if \( i \neq j \) then \( F_i \not\models F_j \).

The intuition behind these conditions is as follows. The first condition guarantees that \( \psi \) defines a partition on the set of finite traces. From the second condition, it follows that if \( t \models P_i \), then for every path \( \pi \) that satisfies \( F_i \), the path \( \pi \) satisfies \( \varphi \) initially. The third condition ensures that if \( t \models P_i \) and \( \pi \) falsifies \( F_i \), the path \( \pi \) falsifies \( \varphi \) initially. The last condition requires that we group together all traces that allow exactly the same future behaviors.

In general, a separation of the formula \( \varphi \) need not satisfy any of these conditions. We first define anchored formulas and prove that anchored \( \varphi \) satisfies (2) and (3) for any formula \( \varphi \). Note that any separation of anchored \( \varphi \) being globally equivalent to anchored \( \varphi \), therefore also satisfies (2) and (3). We then define the notion of a canonical separation to satisfy the remaining two conditions for \( \varphi \).

**Definition 11.** We say an LTL formula \( \psi \) is anchored if, for every path \( \pi \), either \( \pi \models \varphi \) at every time \( i \) or \( \pi \not\models \varphi \) at every time \( i \). For an LTL formula \( \varphi \), we refer to the formula \( \Box \varphi \) as anchored \( \varphi \).

Note that anchored LTL formulas should not be confused with Manna and Pnueli’s “anchored temporal framework” [MP89].

It is immediate that anchored \( \varphi \) is initially equivalent to \( \varphi \). That anchored \( \varphi \) is indeed anchored is entailed by the following lemma.

**Lemma 12.** For every LTL formula \( \varphi \), anchored \( \varphi \) satisfies conditions (2) and (3).

**Proof.** Let \( \pi \in \Sigma^\omega \) and \( i \in \mathbb{N} \) be such that \( \pi, i \models \Box \varphi \). In particular, \( \pi, 0 \models \Box \varphi \) and therefore \( \pi, 0 \not\models \varphi \), proving (2).

Let \( \pi \in \Sigma^\omega \) such that \( \pi, 0 \not\models \varphi \). Then, \( \pi, j \models \Box \varphi \) for every \( j \in \mathbb{N} \).

In particular, for every \( i \in \mathbb{N} \) whenever \( j \leq i \) then also \( \pi, j \models \Box \varphi \). Thus, \( \pi, i \models \Box \varphi \) for every \( i \), proving (3). ▲

We now define a canonical separation that satisfies the remaining two conditions for \( \varphi \). Intuitively, it is a separation that satisfies (1) and (4); moreover, it has a distinguished conjunct with an unsatisfiable future part, and the past part of all other conjuncts is satisfiable. We then constructively prove that such a formula exists, that it can be constructed from any separation, and that all such formulas have the same structure, justifying the name “canonical”.

**Definition 13** (Canonical Separation). For an LTL formula \( \psi \), a canonical separation of \( \psi \) is a separation \( (P \rightarrow \Diamond F) \) that satisfies the following properties:

- For every \( t \in \Sigma^\ast \), there is a unique \( i \) such that \( t \models P_i \).
- For all \( i, j \), if \( i \neq j \) then \( F_i \not\models F_j \).
- There is an \( i \) such that \( F_i \models \bot \).
- If there is an \( i \) such that \( P_i \models \bot \), then \( F_i \models \bot \). ▲

We show that any separation can be transformed into a canonical one. Below, we write \([1, n]\) for the set \([1, \cdots, n]\).

**Construction 14.** Let \((P \rightarrow \Diamond F)\) be any separation of an LTL formula \( \psi \). Consider the formula

\[
\bigwedge_{i \in [1,n]} \left( (\bigwedge_{j \in [1,n]} P_j) \land \left( \bigwedge_{j \in [1,n]} \neg P_j \right) \right) \rightarrow \bigwedge_{i \in [1,n]} F_i.
\]

where \( \bigwedge_{i \in Q} = \top \). We refer to the past and future parts of the conjuncts of this formula by \( P_\ast \) and \( F_\ast \) respectively. Note that the past parts are pairwise inconsistent. It is immediate that this formula is
also a separation of $\psi$. We apply the following transformations, in order:

(i) For every $i$, if $P_i \equiv F_i$, eliminate the conjunct.
(ii) Add the conjunct ($\bot \rightarrow \circ \bot$).
(iii) For every $i$, if there is a $j \neq i$ such that $F_j \equiv F_{j'}$, merge both conjuncts to a single conjunct ($P_j \lor P_{j'} \rightarrow F_j'$).

It is immediate that this process terminates and that the resulting formula is a canonical separation of $\psi$.

Since every separation of any LTL formula is globally equivalent to the formula, it follows from Lemma 12 that any canonical separation of anchored $\varphi$ satisfies conditions (2) and (3). Therefore, for any formula $\varphi$, every canonical separation of anchored $\varphi$ satisfies conditions (1)-(4).

**Example 15.** We construct a canonical separation of anchored $\varphi$ for the precedence property $\varphi = \square(a \rightarrow \lozenge b)$. A separation of anchored $\varphi$ is given by the formula $(P_1 \rightarrow F_1) \land (P_2 \rightarrow F_2)$, where $P_1 = \Box \neg b$, $F_1 = (\neg a \lor b) \lor \lozenge \neg a$, $P_2 = \Box a \land \Box b$, and $F_2 = \bot$. We apply Construction 14 to transform this separation into a canonical separation of anchored $\varphi$, which is the conjunction of the following three formulas:

$$(\Box(a \rightarrow \lozenge b) \land \Box b) \rightarrow \top, \quad (\Box(a \lor b) \lor \Box \neg a, \quad (\Box(a \land \Box b) \land \bot).$$

We are only interested in the semantics of a canonical separation’s conjuncts, and not in their particular syntax. The following theorem states that canonical separations are canonical in the sense that for any formula $\varphi$, all canonical separations of $\varphi$ have the same structure. More precisely, we show that there is no semantic distinction between corresponding conjuncts of two canonical separations of the same formula.

**Theorem 16.** Let $F_1 \equiv F_1$ be an anchored $F_1$ in which the initial state $t_0$ is a member of $\Sigma$. Let $t$ be a trace on $\Sigma$. Then, there is a unique canonical separation of anchored $F_1$.

Proof. Let $F_1 \equiv F_1$ be a conjunct from the first canonical separation such that $F_1$ is satisfiable. Take any trace $t$ such that $t \models F_1$. By the definition of canonical separations, there is a conjunct $P \rightarrow F_1$ in the second canonical separation such that $t \models P$. It follows that for every $i \in [1, n]$, the satisfaction $t_0, i \models \psi$ is equivalent to $P \models F_1$. Therefore, $F_1 \equiv F_1$ are initially equivalent. Assume $P \equiv P_1$. Without loss of generality, let $t' \models P$ and $t' \not\models P$. Then there is another conjunct $P'' \rightarrow F''$, in the first canonical separation such that $t' \models P''$. Now, it follows that $F'' \equiv F''$, but then $F'' \equiv F$, which contradicts the definition of a canonical separation.

In case one of the canonical separations has a conjunct $P \rightarrow F$ such that $P$ is satisfiable and $F \equiv \bot$, it follows that the other separation has such a conjunct as well. Otherwise, both formulas must have a conjunct $\bot \rightarrow \circ \bot$. This gives us the one-to-one correspondence between the conjuncts of both formulas, and thus $n = m$. ▲

To simplify discussions, for any canonical separation, we will use the distinguished index $\bot$ to refer to the conjunct ($P_\bot \rightarrow F_\bot$), where $F_\bot \equiv \bot$.

### 4. Connection to $\omega$-Automata

In this section, we establish a connection between canonical separations of anchored formulas and $\omega$-automata. This will allow us to give upper bounds on the number of conjuncts and the size of the past parts in the separation. Furthermore, we show that separating anchored formulas is elementary if and only if the translation from LTL to FLTL is elementary.

Given a trace $t$ and a formula $\varphi$, a canonical separation $(P \rightarrow F_\bot)$ of anchored $\varphi$ can be used to determine the necessary and sufficient condition for a continuation $\pi$ such that $\pi \models \varphi$. We simply find an index $i$ such that $t \models P_i$ and the condition is given by $F_i$. Let us consider a Büchi automaton $A = (Q, q_0, \Delta, F)$ recognizing $L(\varphi)$, and let $Q_i = \{s' \in Q | (q_0, t, s') \in \Delta_i\}$. The set $Q_i$ consists of all the end states of finite runs of $A$ on $t$. Let $\mathcal{A} = A[q_0 \leftarrow Q_i]$ be the automaton $(Q, Q_i, \Delta, F_i)$, in which the initial state $q_0$ is replaced by the set of states $Q_i$. We show that $Q_i$ characterizes a subset of the set of all traces $t'$ such that $t' \models P_i$, while $\mathcal{A}$ recognizes exactly the paths $\pi$ such that $\pi(0) \models F_i$.

**Theorem 17.** Let $A$ be a Büchi automaton and let $t$ be a trace. A path $\pi$ is accepted by the automaton $\mathcal{A}$ if and only if $t \in L(\mathcal{A})$.

Proof. Assume there is an accepting run $s_0s_1 \cdots$ of $A$ on $t$. It is immediate that $s_0 \in Q_i$, and therefore $s_0 \models \varphi$, which is an accepting run of $\mathcal{A}$ on $\pi$. Conversely, let $\pi \in L(\mathcal{A})$, and let $s_0s_1 \cdots$ be an accepting run on $\pi$. By definition, $s_0 \in Q_i$, and therefore there is a finite run $p_0p_1 \cdots p_0$ of $A$ on $t$ such that $p_0 \models \varphi$. It follows that $p_0p_1 \cdots p_0s_1 \cdots$ is an accepting run of $A$ on $\pi$. ▲

This establishes a connection between Büchi automata and a canonical separation of anchored $\varphi$, as stated in the following corollaries.

**Corollary 18.** Let $\varphi$ be an LTL formula and let $(P \rightarrow F_\bot)$ be a canonical separation of anchored $\varphi$. For any automaton $A$ recognizing $\varphi$, the following holds.

$$\forall t \in \Sigma, \forall i \in [1, n], t \models P_i \implies L(\mathcal{A}) = L(F_i).$$

**Corollary 19.** Let $\varphi$ be an LTL formula and let $(P \rightarrow F_\bot)$ be a canonical separation of anchored $\varphi$. For any automaton $A$ recognizing $\varphi$ and any two traces $t, t' \in \Sigma^*$ the following holds.

$$L(\mathcal{A}) = L(F_i) \implies \forall i \in [1, n], t \models P_i \iff t' \models P_i.$$
Intuitively, $\varphi$ requires that all four combinations of truth values of $a$ and $b$ occur infinitely often. A canonical separation of anchored $\varphi$ is given by $(T \rightarrow \square \varphi) \land (\perp \rightarrow \square \perp)$. It is immediate that all finite traces satisfy the same past part, namely $\top$.

A Büchi automaton with the least number of states recognizing $\varphi$ is given in Fig. 1. Even though all traces are equivalent with respect to the satisfaction of $\varphi$, the automaton has one non-accepting state for each combination of truth values of $a$ and $b$, as well as an additional accepting state that serves to monitor that the four combinations all occur infinitely often.

While the separation gap is believed to be nonelementary [HR05], the connection between a canonical separation and ω-automata allows us to prove elementary bounds on the number of conjuncts and the size of the past parts of a canonical separation of anchored LTL formulas. Furthermore, we show that the size of the future parts is related to the succinctness gap between LTL and FLTL, and the size of the past parts of a canonical separation of anchored LTL formulas is elementary, there is an elementary bound on the succinctness gap between LTL and FLTL.

To prove the converse, we show that the size of the future parts is elementary in the size of $\varphi^\omega$. This, together with Theorems 21 and 22, proves our claim. So, assume that there is an elementary bound on the size of $\varphi^\omega$. For every index $i$ and trace $t = t_0 t_1 \cdots t_{n-1}$ such that $t \models P_i$, we know that $\tau_n, 0 \models \varphi^\omega$ if and only if $\pi, 0 \models F_i$. Intuitively, we will “partially evaluate” the satisfaction of $\varphi^\omega$ on the trace $t$ to obtain $F_i$. The procedure is similar to semantic tableaux for LTL. Every formula of the form $\psi_1 \cup \psi_2$ is equivalent to the formula $\psi_2 \lor (\psi_1 \land (\psi_1 \psi_2))$. Using this equivalence, we can rewrite $\varphi^\omega$ to a formula in which only propositional formulas are not under the scope of the next time connective $\square$. Since $\varphi^\omega$ contains no past temporal connectives, the satisfaction of all formulas under the scope of the next time connective is independent of $t_0$.

We can therefore replace each formula $\varphi$ that is not under the scope of $\square$ with $\top$ if $t_0 \models a$, and with $\perp$ if $t_0 \not\models a$. We then rewrite the resulting formula to $\square \varphi^\omega$. It is immediate that $\tau_n, 0 \models \varphi^\omega$ if and only if $\pi, 0 \models \varphi^\omega$. We continue this procedure for the entire $t$, and ultimately get $\tau_n, 0 \models \varphi^\omega$ if $\pi, 0 \models \varphi^\omega$. Therefore $\varphi^\omega \equiv F_i$. Note that, due to Corollary 19, one can always choose a trace $t$ such that $t \models P_i$ and the length of $t$ is at most double exponential in the size of $\varphi$.

To conclude the proof, we show that the size of $\varphi^\omega$ is at most exponential in $|\varphi^\omega|$. For any formula $\psi$, we define the set of subformulas of $\psi$, denoted $\text{SF}(\psi)$, inductively as follows. $\text{SF}(\top) = \{\top\}$, $\text{SF}(\varphi) = \{\varphi\}$ for $\varphi \in \{\land, \lor, \neg\}$, and $\text{SF}(\psi_1 \bullet \psi_2) = \{\psi_1 \bullet \psi_2\} \cup \text{SF}(\psi_1) \cup \text{SF}(\psi_2)$ for $\bullet \in \{\land, \lor, \neg\}$.

We are ready to prove our main theorem.

Theorem 23. The following statements are logically equivalent:

(a) The separation gap for anchored LTL is elementary.

(b) The succinctness gap between LTL and FLTL is elementary.

Proof. One direction is immediate. Take an arbitrary LTL formula $\varphi$. First, we anchor and then separate $\varphi$. Second, in every past formula in the separation, we iteratively replace $\psi_1 S \psi_2$ by $\psi_2$ and $\psi_1 \psi$ by $\perp$. This results in an FLTL formula, denoted $\varphi^\omega$, that is initially equivalent to $\varphi$. The size of $\varphi^\omega$ is clearly smaller than the size of the separation. Therefore, assuming that the separation gap for anchored LTL formulas is elementary, there is an elementary bound on the succinctness gap between LTL and FLTL.

In Section 3, we formalized how finite traces determine future behavior with respect to properties expressed by LTL formulas. Here, we generalize this idea to arbitrary properties. We show in Section 5.1 that, for any property $L$, this reasoning can be formalized as an equivalence relation, denoted $\equiv_L$. Furthermore, the safety closure of $L$ and the condition for $L$ to be a liveness
property can be characterized in terms of equivalence classes of \( \equiv_L \).

In Section 5.2, we turn to safety-liveness decomposition in LTL.

5.1 Decomposition of Arbitrary Properties

For a property \( L \) we define an equivalence relation \( \equiv_L \) that relates two finite traces \( u \) and \( v \) if for every infinite continuation \( \pi \) either both \( u \pi \) and \( v \pi \) satisfy the property (i.e. both belong to \( L \)), or both falsify it. Intuitively, two finite traces are equivalent if they place the same restrictions on future behaviors.

**Definition 24.** Let \( L \) be a property. We define the equivalence relation \( \equiv_L \subseteq \Sigma^* \times \Sigma^* \) as follows.

\[
u \equiv_L v \text{ if } \forall \tau \in \Sigma^*, (u \pi \in L \iff v \pi \in L).
\]

\( \triangle \)

**Definition 25 ([N58]).** An equivalence relation \( \approx \) on a set of traces \( \Sigma^* \) is right invariant with respect to concatenation if for all traces \( u, v, z \in \Sigma^* \), \( u \approx v \) implies \( u \pi \approx v \pi \).

It is immediate that \( \equiv_L \) is right invariant. For a property \( L \), if there is a trace \( v \in \Sigma^* \) such that \( v \pi \not\in L \), for every \( \pi \in \Sigma^* \), we define the set \( L_\pi \) of irreducible traces as the equivalence class \( [v]_{\equiv_L} \).

Otherwise, we define \( L_\pi = \emptyset \). The safety closure of \( L \) and the condition for \( L \) to be a liveness property can be characterized using \( L_\pi \).

**Lemma 26.** For every property \( L \), its safety closure \( [L] \) is the set \( \{ \pi \in \Sigma^* | \forall i \in \mathbb{N}, \pi_i \not\in L_i \} \).

**Proof.** We show that \( \equiv_L \subseteq \Sigma^* \times \Sigma^* \) is a safety property containing \( L \), and that it is a subset of every other such property. It follows that \( \equiv_L \subseteq [L] \).

For any path \( \pi \not\in L \), there is an \( i \in \mathbb{N} \) such that \( \pi_i \not\in L \). It follows that either \( \pi_i \not\in L \) for every path \( \sigma \) and therefore \( \pi \not\in [L] \). Finally, let \( S \) be a safety property containing \( L \). Then, for every path \( \pi \not\in S \), there is an \( i \in \mathbb{N} \) such that \( \pi_i \not\in S \), for every \( \sigma \) in \( \pi \). Since \( \pi \not\in S \), also \( \pi_i \not\in L \). Therefore, \( \pi_i \not\in L_i \) and thus \( \pi \not\in [L] \).

The following proposition shows that for any property \( L \), the relation \( \equiv_L \) is a refinement of \( \equiv_{[L]} \).

**Proposition 27.** For any property \( L \) and any \( u, v \in \Sigma^* \) if \( u \equiv_L v \), then \( u \equiv_{[L]} v \). Furthermore, \( L_\pi = [L_\pi] \).

**Proof.** Let \( \equiv_L \subseteq \Sigma^* \times \Sigma^* \), and let \( \pi \in \Sigma^* \) be an arbitrary path. Since \( \equiv_L \) is right invariant, it follows that for every \( i \in \mathbb{N} \) also \( \equiv_L \subseteq \Sigma^* \). Therefore, \( \equiv_L \subseteq \Sigma^* \).

For a trace \( u \in L \), it is immediate that \( \equiv_L \subseteq \Sigma^* \). Therefore also \( \equiv_{[L]} \subseteq \Sigma^* \). Conversely, if \( \pi \in [L] \), then for every path \( \pi \) it follows that \( \pi \not\in [L] \) and, since \( L \subseteq [L] \), also \( \pi \not\in L \).

Intuitively, this proposition states that every property can be defined by first choosing the set of finite irreducible traces (safety closure), and then refining this safety property by excluding some infinite paths (intersection with liveness). The following characterization of liveness follows immediately from the definition of \( L_\pi \).

**Lemma 28.** \( L \) is a liveness property if and only if \( L_\pi = \emptyset \).

\( \triangle \)

5.2 Decomposition in LTL

For an LTL formula \( \varphi \) we define the sets

\[ C_i = \{ t \in \Sigma^* | t \models P_i \}, \]

where \( P_i \) is the past part of the \( i \)-th conjunct of a canonical separation of anchored \( \varphi \). For an index \( i \) and a trace \( t \in C_i \), we have \( t_0 \models \varphi \) if \( \pi_0 \models F_i \). Thus, if \( t \in C_i \), it follows that \( t \models (t \models F_i) \).

Since a canonical separation cannot have two conjuncts with equivalent future parts, if \( t \in C_i \) and \( t' \not\in C_i \), it follows that \( t \not\models (t \models F_i) \).

This proves the following theorem; recall that \( \triangle \) is the distinguished index that refers to the conjunct where \( F_i \equiv \triangle \).

**Theorem 29.** Let \( \varphi \) be an LTL formula and let \( L(\varphi) \) be the property expressed by \( \varphi \). The equivalence classes of the relation \( \equiv_{L(\varphi)} \) are given by the sets \( C_i \) and \( \equiv_{L(\varphi)} \) is of finite index. Furthermore, \( L(\varphi)_\triangle = C_\triangle \).

**Example 30.** The precedence property expressed by \( \varphi = \Box(a \rightarrow \Diamond b) \) can be written as the following \( \omega \)-regular expression.

\[ L(\varphi) = (\neg a \land \neg b)^* \Sigma^+ \lor (a \land \neg b)^*. \]

Consider the sets \( C_1 = (\neg a \land \neg b)^* \Sigma^+ \), \( C_2 = (\neg a \land \neg b)^* \), and \( C_3 = (a \land \neg b)^* \Sigma^+ \). It is straightforward to prove that these sets correspond to the equivalence classes of the relation \( \equiv_{L(\varphi)} \).

Furthermore, \( C_3 = L(\varphi)_\triangle \), because every trace in \( C_3 \) is clearly irreducible. In particular, from Lemma 28 it follows that \( \varphi \) is not a liveness formula. Note that the equivalence classes correspond to the past parts of the three formulas of the canonical separation of Example 15.

Theorem 29 establishes a connection between the relation \( \equiv_{L(\varphi)} \) and any canonical separation of anchored \( \varphi \). Constructions of the safety closure and the safety-liveness decomposition theorem for LTL formulas are now immediate consequences of Lemma 26 and Theorem 29.

**Theorem 31.** Let \( \varphi \) be an LTL formula. The safety closure of the property \( L(\varphi) \) is the property \( L(\varphi)_\triangle \), expressed by the LTL formula \( \varphi_\triangle := \Box \neg P_\triangle \).

**Proof.** Take the correspondence of Lemma 26. We claim that \( \varphi \equiv_{L(\varphi)} \).

From \( \varphi \equiv_{L(\varphi)} \), then for every path \( i \in \mathbb{N} \) such that \( \pi_i \not\in L(\varphi)_\triangle \), \( \pi \not\in L(\varphi)_\triangle \).

The following lemma establishes that if a trace is irreducible for some formula, it cannot also be irreducible for its negation.

**Lemma 32.** For any LTL formula \( \varphi \), \( L(\neg \varphi)_\triangle \subseteq L(\varphi)_\triangle \).

**Proof.** Let \( t \in L(\neg \varphi)_\triangle \). Then, for an arbitrary path \( \pi_i, 0 \not\models \neg \varphi \), which is equivalent to \( t_0, 0 \not\models \varphi \). It is immediate that \( t \not\models L(\varphi)_\triangle \).

Note that the converse inclusion is generally false: take \( \varphi = a \land a \) and \( t = aa \). For the path \( \pi_i = a^\omega \), we have \( \pi_i, 0 \not\models \varphi \) and therefore \( t \not\models L(\neg \varphi)_\triangle \).

**Theorem 33.** Let \( \varphi \) be an LTL formula. The formula \( \varphi := \neg \neg \varphi \) is a liveness formula.

**Proof.** It is immediate that \( L(\varphi)_\triangle = L(\varphi)_\triangle \land L(\neg \varphi)_\triangle \).

From Lemma 32, it follows that \( L(\neg \varphi)_\triangle \subseteq L(\varphi)_\triangle \).

Therefore, from Proposition 27, it follows that \( L(\neg \varphi)_\triangle \subseteq L(\varphi)_\triangle \).

Thus, \( L(\varphi)_\triangle \subseteq \emptyset \) and by Lemma 28, the formula \( \varphi \) is liveness.

Theorem 33 states that any formula \( \varphi \) that is not a safety formula is uniquely equivalent to the conjunction of a safety LTL formula and a liveness LTL formula, given by \( \varphi \) and \( \varphi \), respectively.

**Corollary 34.** (Safety-Liveness Decomposition in LTL). Every LTL formula \( \varphi \) is initially equivalent to the conjunction of a safety LTL formula and a liveness LTL formula, given by \( \varphi \) and \( \varphi \), respectively.
These results can be used to construct a Büchi automaton accepting $L(\varphi)$. We first use the Myhill-Nerode theorem \([N58]\) to construct a minimal DFA recognizing all the equivalence classes except $C_1$. Note that by changing the acceptance condition of an automaton $A = (Q, q_0, \Delta, F)$ on finite words, we can see it as a Büchi automaton. To satisfy the conditions of the Myhill-Nerode theorem, we extend $=_{\pi, \varphi}$ to encompass the empty word $\varepsilon$ as follows. If there is an index $i$ such that $\varphi \equiv F_i$, then we define $e \in C_i$; otherwise we define $e \not\in C_i$ for every nonempty trace $t \in \Sigma^*$. 

**Proposition 35.** Let $\varphi$ be an LTL formula and $M$ be the minimal DFA recognizing the union of equivalence classes of $=_{\pi, \varphi}$ other than $C_1$. Then the automaton $M$ considered as a Büchi automaton recognizes $L(\varphi)$.

**Corollary 36.** Let $\varphi$ be a safety LTL formula and $M$ be the minimal DFA recognizing the union of equivalence classes of $=_{\pi, \varphi}$ other than $C_1$. The automaton $M$ considered as a Büchi automaton recognizes $L(\varphi)$. Furthermore, it is minimal in the sense that it is the deterministic Büchi automaton recognizing $L(\varphi)$ with the least number of states.

**Proof.** Since $\varphi$ is safety, it follows that $[\varphi] \equiv \varphi$ and $M$ recognizes $L(\varphi)$, by Proposition 35.

For any deterministic Büchi automaton recognizing $\varphi$ and any trace $t \in \Sigma^*$, the set $Q_t$ is a singleton set. From Corollary 18, such an automaton must have at least $n$ states, since $(P \to \bigcirc F)_n$ has $n$ conjuncts. Furthermore, if $\varphi \not\equiv F_i$ for every index $i$, then there is no trace $t$ such that $Q_t = \{q_0\}$, and the automaton must have at least $n + 1$ states. This is exactly the number of states of $M$, proving that it is minimal.

**Example 37.** Consider the formula $\varphi = \square(a \lor (b \land c))$. For example, the property expressed by $\varphi$ could state that access to a resource is not allowed (a) unless an authorized user logged into the system (c) and has been active since (b). Without going into the details of the separation procedure, we separate anchored $\varphi$, and use Construction 14 to obtain a canonical separation. The canonical separation of anchored $\varphi$ consists of three conjuncts. The past and future parts are given below.

- $P_1 = \blacksquare(a \lor (b \land c)) \land \neg(b \land c)$,
- $F_1 = (\blacksquare a \lor (a \lor U c)) \land \blacksquare b \lor \blacksquare a \lor (a \lor U c))$,
- $P_2 = \blacksquare(a \lor (b \land c)) \land (b \land c)$,
- $F_2 = \blacksquare (b \lor a \lor (a \lor U c))$,
- $P_3 = \neg(a \lor (b \land c))$,
- $F_3 = \bot$.

The safety closure of $\varphi$ is given by $\square \neg P_3 \equiv \blacksquare(a \lor (b \land c))$. It is easy to verify that the equivalence classes of the relation $\approx_{\pi, \varphi}$ are given by the following regular expressions.

- $C_1 = ((a + cb^*) (a \land \neg b \land \neg c) + e) (a \land \neg c)^*$,
- $C_2 = (a + cb^*) (cb^*)$,
- $C_3 = C_1 + C_2$.

The construction of the minimal deterministic Büchi automaton recognizing $\varphi$ is now simple. The set of states is $Q = \{p_1, p_2, p_\bot\}$, where the index determines the corresponding equivalence class. The set of accepting states is $F = \{p_1, p_2\}$, and since $e \in C_1$, the initial state is $p_1$. Now, for each $a \in \Sigma$ and every state $q_i$, we take a trace $t \in C_i$ and define $A(p_i, a) = p_j$ if $t a \in C_j$. The automaton is given in Fig. 2.

**6. Characterizing Classes of Temporal Properties**

In this section, we use canonical separation of anchored formulas to characterize liveness, safety, stable, absolute liveness, and fairness properties. We also show that recognizing properties in these classes in LTL can be reduced to deciding LTL validity. We start with characterizing safety and liveness in LTL.

**Theorem 38** (Characterization of Liveness). A formula $\varphi$ is liveness if and only if the formula $\square \varphi \lor P_3$ is not satisfiable, i.e. $\square P_3 \equiv \bot$.

**Proof.** From Lemma 28 and Theorem 29 it follows that $\varphi$ is liveness if every trace $t \in \Sigma^*$ falsifies $P_3$. This is equivalent to the condition that, for every path $\pi \in \Sigma^*$ and every $i \in \mathbb{N}$, $\pi_i \not\models \neg P_3$. Thus, $\varphi$ is liveness iff $\pi, 0 \not\models \square \neg P_3$ for every path $\pi$, and therefore also $\pi, 0 \not\models \square P_3$.

As a consequence, we obtain for LTL the following well-known result from [AS85].

**Corollary 39.** A formula $\varphi$ is liveness if and only if $[\varphi] \equiv \top$.

A formula $\varphi$ is safety if and only if the property $L(\varphi)$ is equal to $L(\square \neg P_3)$. In other words, $\varphi$ is safety iff $\varphi \equiv \square \varphi$. From Theorem 31 it follows that $L(\varphi) \subseteq L(\square \neg P_3)$. Therefore, it suffices to show that there is no path $\pi \in \Sigma^*$ such that $\pi, 0 \not\models \square \neg P_3$ and $\pi, 0 \not\models \varphi$. This gives us the following characterization of safety.

**Theorem 40** (Characterization of Safety). A formula $\varphi$ is safety if and only if the formula $\neg \varphi \lor \square \neg P_3$ is not satisfiable.

To illustrate these results, we return to our running example.

**Example 41.** Consider again $\varphi = \square(a \to \diamond b)$. In Example 30, we gave a canonical separation of anchored $\varphi$. It is immediate that $P_1 = \blacksquare(a \land \neg b)$, Consider the formula $\blacksquare(a \land \neg b)$. This formula is satisfiable, for example by the path $a^\omega$. Therefore, $\varphi$ is not liveness. We can explicitly construct the safety closure of $\varphi$ as

$[\varphi] = \square \neg \blacksquare(a \land \neg b)$.

This formula is globally equivalent to $\blacksquare (a \land \neg b)$, and initially equivalent to $\square(a \to \diamond b)$. Therefore, the formula $\neg \varphi \lor [\varphi]$ is not satisfiable, proving that $\varphi$ is a safety property.

We next characterize stable, absolute liveness, and fairness properties in LTL. We follow Sistla’s definitions for these properties [S94].
Definition 42. Let \( \varphi \) be an LTL formula.

1. \( \varphi \) is stable if for every path \( \pi \), the initial satisfaction \( \pi, 0 \models \varphi \) implies \( \pi, i \models \varphi \), for all \( i \in \mathbb{N} \).
2. \( \varphi \) is absolute liveness if \( \varphi \) is satisfiable, and for all traces \( t \) and every path \( \pi \) such that \( \pi, 0 \models \varphi \), then \( \pi, n \models \varphi \).
3. \( \varphi \) is fairness if it is both stable and absolute liveness. △

Intuitively, a fairness property can neither be satisfied nor falsified in finite time. Note that Sistla’s definition of stable properties, stating that \( \pi, i \models \varphi \) implies \( \pi, i+1 \models \varphi \), differs slightly from ours. The two definitions coincide for FLTL, but the modification above is necessary to formalize a stable property as a property containing all suffixes of its elements in LTL.

Let \( \varphi \) be an LTL formula and let \( (P \rightarrow \circ F_i) \) be a canonical separation of anchored \( \varphi \). We first give necessary and sufficient conditions for \( \varphi \) to be stable and absolute liveness. We combine them to characterize fairness and conclude the section with an example.

For any past formula \( \psi \), we can find an initially equivalent propositional formula. We just iteratively replace \( \psi \rightarrow S \psi \) by \( \exists \psi \) and \( \otimes \psi \) by \( \exists \psi \). For every past part \( P_i \), let us denote this propositional counterpart by \( N_i \).

The intuition for the following theorems is as follows. Let \( \pi \) be a path satisfying a stable formula \( \varphi \) and consider a canonical separation of anchored \( \varphi \). Then for any \( i \) there is an index \( j \) such that \( \pi, k \models P_i \) and \( \pi, k \models \circ F_i \). If we remove a prefix of \( \pi \) of length \( k \), it is possible that \( \pi^k, 0 \models P_i \), i.e., \( \pi, k \models N_i \), for some \( j \neq i \). In this case, it is necessary that \( \pi, k \models \circ F_i \) for \( \varphi \) to be stable. Analogous intuition holds for absolute liveness.

Theorem 43. A formula \( \varphi \) is stable if and only if the formula \( \Psi_1(\varphi) = \bigvee_{i=1}^k \otimes (P_i \land N_i \land \circ F_i \land \circ \neg F_i) \) is not satisfiable.

Proof. Let \( \varphi \) be stable and assume the contrary, i.e., there is a path \( \pi \in \Sigma^\omega \) such that \( \pi, 0 \models \Psi_1(\varphi) \). Then there exists a \( k \geq 0 \) and indices \( i, j \) such that \( \pi, i \models P_i \), \( \pi, i \models N_i \), \( \pi, i \models \circ F_i \), and \( \pi, j \models \circ \neg F_j \). Since \( \pi, k \models P_i \) and \( \pi, k \models \circ F_i \), it follows that \( \pi, 0 \models \varphi \). From \( \pi, k \models N_i \), it follows that \( \pi^k, 0 \models P_i \). Since \( \pi, k \models \circ \neg F_j \), we also have \( \pi^k, 0 \models \neg \circ F_j \) and \( \pi^k, 0 \not\models \varphi \). This contradicts the assumption that \( \varphi \) is stable.

To prove the converse, suppose \( \Psi_1(\varphi) \) is not satisfiable and \( \varphi \) is not stable. Then, there exists a path \( \pi \in \Sigma^\omega \) such that \( \pi, 0 \models \varphi \) and \( \pi \models \neg \sigma \). Let \( i \) and \( j \) be indices such that \( \pi, i \models N_i \) and \( \pi, j \models N_j \). It follows that \( \pi^k, 0 \models \circ F_i \) and \( \pi^k, 0 \not\models \circ F_j \). Therefore, \( \pi, k \models P_i \land N_i \land \circ F_i \land \circ \neg F_j \), and \( \pi, 0 \not\models \Psi_1(\varphi) \), which is a contradiction. ▲

Example 44. Let \( \varphi = \sigma a \). A canonical separation of anchored \( \varphi \) is \( (\sigma \rightarrow a \rightarrow o) \land (\sigma a \rightarrow o \sigma a) \). To prove \( \varphi \) is a stable formula, by Theorem 43 we show that the formulas \( \sigma (\sigma \rightarrow a \land a \rightarrow o \land a \sigma a) \) and \( \sigma (\sigma a \land a \rightarrow o \land a \sigma a \rightarrow o \land \sigma a) \rightarrow o \land a \sigma a) \) are not satisfiable. This is immediate because of the \( \sigma o \) in the first formula and \( \sigma a \land a \rightarrow o \land a \sigma a) \) in the second formula. △

The proof of the following theorem is similar to the proof of Theorem 43.

Theorem 45. A formula \( \varphi \) is absolute liveness if and only if the formula \( \Psi_2(\varphi) = \bigvee_{i=1}^k \otimes (P_i \land N_i \land \neg \circ F_i \land \circ F_i) \) is not satisfiable and \( \varphi \) is satisfiable. ▲

Example 46. Let \( \varphi = \sigma a \). A canonical separation of anchored \( \varphi \) is \( (\sigma \rightarrow o \land o \rightarrow o \land a) \). It is immediate that \( \varphi \) is a liveness formula, and therefore satisfiable. It is absolute liveness, by Theorem 45 we show that \( \Psi_2(\varphi) \) is not satisfiable. Since \( P_i = o \), we need only consider indices \( i, j \neq i \). The two formulas we must check are \( \sigma (\sigma a \land a \rightarrow o \land o \rightarrow o \land a) \) and

<table>

</tbody>
</table>

\( \bigvee (\neg a \land a \land o \land o \land a \land o \land T) \). It is immediate that neither formula is satisfiable. △

Combining the characterizations of stable and absolute liveness properties results in a simple characterization for fairness.

Theorem 47. A formula \( \varphi \) is fairness if and only if a canonical separation of anchored \( \varphi \) is of the form \( (\Sigma \rightarrow o \land o \rightarrow o \land a) \) for some future formula \( F \).

Proof. Let \( \varphi \) be fairness. In particular, \( \varphi \) is liveness, satisfiable, and \( \neg P_i \). Assume that there are indices \( i \neq j \) and traces \( u, v \in \Sigma^* \) such that \( u \models P_i \) and \( v \models P_j \). The formula \( F \) is then satisfiable and let \( \pi \) be a path such that \( \pi, 0 \models F \). Then \( ur, v \models \varphi \). Since \( \varphi \) is stable, it follows that \( \pi, 0 \models \varphi \). Since \( \varphi \) is absolute liveness, \( \pi \models \varphi \). Therefore, \( \pi, 0 \models F \). By repeating this proof with the indices exchanged, we get that \( F \) and \( \neg P_i \) are equivalent, contradicting the initial assumption.

For the converse, the canonical separation satisfies the conditions of Theorem 43 and Theorem 45. It is thus immediate that \( \varphi \) is both stable and absolute liveness. ▲

Corollary 48 (Characterization of Fairness). A formula \( \varphi \) is fairness if it is satisfiable and there is an index \( i \) such that \( \neg P_i \). ▲

Corollary 49. A formula \( \varphi \) is fairness if and only if a canonical separation of anchored \( \varphi \) is of the form \( (\Sigma \rightarrow o \land o \rightarrow o \land a) \) where \( F \equiv \varphi \).

This characterization implies that the LTL formula of Example 20 expresses a fairness property.

Corollary 50. Recognizing safety, liveness, absolute liveness, stable and fairness properties can be reduced to the UNSAT problem for LTL, summarized in Table 1. ▲

A formula \( \varphi \) of LTL expresses a safety, liveness, absolute liveness, stable or fairness property if the respective formula in Table 1 is not satisfiable. Note that the characterization of absolute liveness additionally requires that \( \varphi \) is satisfiable, but one can instead show that \( \varphi \) is liveness. This is justified since every absolute liveness formula is a liveness formula, and every liveness formula is satisfiable.

7. Related Work

The canonical separation of anchored formulas is inspired by the (declarative) past implies (imperative) future paradigm of [G87], which was used for the separated normal form (SNF) of Fisher [F97] and is the underlying idea of MetaTeM [F92]. Intuitively, SNF is a set of rules that describe which actions a system has to make at the current time with respect to observations it has made in the previous steps. Our reasoning is based on finite traces, while with SNF one can only reason about the current moment in time, which makes it necessary to start at the initial time 0.
Concerning the complexity of translating LTL to FLTL, a nonelementary algorithm can be obtained using the separation rewrite rules from [G87]. Hodkinson and Reynolds [HR05] state that it is not clear whether this can be done without separation. An elementary, but inefficient, algorithm for the translation certainly exists if the succinctness gap is elementary. One can just check initial equivalence with respect to FLTL formulas of increasing size until a match is found.

It appears that the existence of an elementary bound on the succinctness gap has become folklore. Since \( \omega \)-automata recognizing the language of any LTL formula can be efficiently constructed, an elementary translation from \( \omega \)-automata to FLTL would answer the question. Several authors have proposed using a translation by Wilke [W99] for this purpose. However, Wilke considers FLTL on finite traces and generalizing the translation to FLTL on infinite paths is not obvious. Gastin and Oddoux [GO01] generalize Wilke’s result to infinite words, but their construction uses first order logic as an intermediary step, which incurs a nonelementary blow-up. Maler and Pnueli [MP94] give a translation from Muller automata to LTL, but they use past temporal connectives. These formulas can be translated to FLTL using Pnueli and Zuck’s algorithm [PZ93]; the algorithm is however nonelementary.

Sistla [S94, S85] characterizes safety, stable, absolute liveness, fairness, and other properties in FLTL, leaving the characterization of liveness as an open problem. He also gives a decision procedure for recognizing safety and liveness in FLTL and characterizes various properties in less expressive sub-logics of FLTL. Lichtenstein et al. [LPZ85] characterize safety in LTL, but their characterizations do not result in a decision procedure. They also characterize “liveness”, but their definition of liveness differs from Alpern and Schneider’s (which we follow here). Manna and Pnueli [MP87] use Gabbay’s separation to characterize liveness properties in LTL, resulting in a characterization similar to ours. We are not aware of any characterizations of stable, absolute liveness, and fairness properties in LTL.

Concerning the safety-liveness decomposition, Alpern and Schneider [AS85] prove that every property is an intersection of a safety and a liveness property. Moreover, they show that \( \omega \)-regular properties, i.e. the properties accepted by Büchi automata, can be decomposed as an intersection of a safety \( \omega \)-regular property and a liveness \( \omega \)-regular property [AS87]. Their decomposition does not readily translate to LTL. This is because LTL formulas are only capable of expressing star-free \( \omega \)-regular languages, which constitute a strict subset of \( \omega \)-regular languages [W83].

In previous work [PMTDB], we prove that the safety-liveness decomposition is possible in FLTL using counter-free Büchi automata. The argument relies on a special case of a translation from counter-free DFA to FLTL on finite words [W99] and the notion of protected formulas from [PZ93]. The construction of the safety closure we present here is elementary, in contrast to the nonelementary construction in [PMTDB].
